DESCRIPTION

NONLINEAR CIRCUIT, RADIO COMMUNICATION APPARATUS, AND
NONLINEAR AMPLIFICATION METHOD

5

Technical Field

[0001] The present invention relates to a radio communication apparatus and a nonlinear circuit provided in a radio communication apparatus, and also a nonlinear amplification method implemented by this nonlinear circuit and so forth.

Background Art

[0002] Heretofore, in amplifiers, modulators, or the like provided in radio communication apparatuses, nonlinear elements have been used for which a variation in the applied voltage or applied current and the variation arising therefrom are not directly proportional.

Generally, if the power supply voltage is constant, a nonlinear circuit equipped with nonlinear elements exhibits higher distortion and higher efficiency as output power increases, and conversely, exhibits lower distortion and lower efficiency as output power decreases, as shown in FIG.1. Also, as can be seen from FIG.1, if output power is constant, a nonlinear circuit exhibits higher distortion and higher efficiency as the power supply voltage decreases, and conversely, exhibits lower

distortion and lower efficiency as the power supply voltage increases.

- [0003] Extension of communication time and standby time by suppressing power consumption, as well as improvement of communication quality, are required of radio communication apparatuses, and more particularly mobile communication terminal apparatuses such as mobile phones, equipped with nonlinear circuits. This is the same as requiring radio communication apparatuses to amplify transmit/receive signals with high efficiency and low distortion. However, since high efficiency and low distortion are conflicting characteristics for a nonlinear circuit, as is clear from FIG.1, it is difficult to implement a radio communication apparatus that satisfies both these characteristics at the same time. Furthermore, the amount of distortion that occurs when a transmit/receive signal is amplified varies according to the transmit/receive signal modulation method, signal level (power level), and so forth, and therefore it is necessary for a radio communication apparatus to adaptively adjust the applied voltage or applied current supplied to the amplifier, or the amplifier gain and so forth, according to variations in these nonlinear circuit and similar operating conditions.
- 25 [0004] In order to perform highly efficient, low-distortion amplification of transmit/receive signals in a conventional radio communication apparatus,

a technology is generally used that permits distortion generated by a nonlinear circuit up to a stipulated value upper limit of the radio communication system specification, and also lowers the applied power supply voltage. For example, there are known a technology that takes a set standard for the power supply voltage supplied to a nonlinear circuit as the output power from this nonlinear circuit or the input power to this nonlinear circuit, and a technology that monitors the signal level 5 of a transmit/receive signal input to a nonlinear circuit, and adaptively adjusts the applied voltage according to the peak power to average power ratio of that transmit/receive signal, and its modulation method or modulation speed (see Patent Document 1, Patent Document 10 15, and Patent Document 3).

[0005] FIG.2 is a block diagram showing the configuration of a conventional general nonlinear circuit 10. This nonlinear circuit 10 has a transmit/receive signal input terminal 11, an amplifier 12, a transmit/receive signal output terminal 13, a power supply set value input terminal 20 14, and a power supply control unit 15.

[0006] FIG.3 is a timing chart showing the voltage, etc., in each component part of nonlinear circuit 10 when the slots shown in line L701 (ai-1, ai, ai+1, ai+2) are input 25 from transmit/receive signal input terminal 11 of nonlinear circuit 10 to amplifier 12. In FIG.3, line L702 shows amplifier 12 per-slot output power target values

(P_{i-1} , P_i , P_{i+1} , P_{i+2}), line L703 shows power supply control unit 15 per-slot applied voltage set values (V_{i-1} , V_i , V_{i+1} , V_{i+2}), and line L704 shows the applied voltages actually supplied from power supply control unit 15 to amplifier 12. Power supply control unit 15 should ideally supply the applied voltages shown in line L703 to amplifier 12, but when the configuration of power supply control unit 15 includes a DC-DC converter or the like, the actual applied voltage cannot keep pace with transitions of the set value, and therefore time lag periods ($T_{resp,i}$, $T_{resp,i+1}$, $T_{resp,i+2}$) occur as shown in line L704.

[0007] FIG.4 shows an example of the relationship between output power and applied voltage for amplifier 12. Generally, in amplifier 12, since the output signal itself is an operating condition for performing highly efficient operation while satisfying the distortion permitted by the radio communication system specification, there is a trend for the power supply voltage that must be applied to increase as the output power increases.

[0008] Next, the operation of nonlinear circuit 10 will be described, referring to FIG.2, FIG.3, and FIG.4 as appropriate. A transmit/receive signal input to transmit/receive signal input terminal 11 is amplified by amplifier 12, and then output to transmit/receive signal output terminal 13. On the other hand, information on the power to be output by amplifier 12 (including the amplifier 12 output power target value) is input from

power supply set value input terminal 14 to power supply control unit 15. Power supply control unit 15 adjusts the power supply voltage applied to amplifier 12 based on the input amplifier 12 output power target value after
5 taking the characteristic shown in FIG.4 into consideration. Since the signal level of the transmit/receive signal input to amplifier 12 varies on a slot-by-slot basis as shown in line L701, the amplifier 12 output power target value also varies serially in
10 accordance with transitions of the signal level of the input transmit/receive signal. Power supply control unit 15 adjusts the power supply voltage applied to amplifier 12 in accordance with these amplifier 12 output power transitions, but due to the characteristics of the
15 DC-DC converter provided in power supply control unit 15, the applied voltage variation time lag periods ($T_{resp,i}, T_{resp,i+1}, T_{resp,i+2}$) shown in line L704 occur.
[0009] In a time lag period that arises because the actual applied voltage cannot keep pace with transitions of the
20 applied voltage set value as shown in line L704 (which may hereinafter be referred to as a "transient period"), the applied voltage actually supplied from power supply control unit 15 to amplifier 12 naturally deviates from the applied voltage set value shown in line L703, and
25 therefore transmit/receive signal distortion may increase as regards the amplifier 12 output power.
However, since transmit/receive signal distortion caused

by amplification by amplifier 12 is averaged time-wise in the transmit/receive signal slot units shown in line L701, if transient periods are short the increase in transmit/receive signal distortion is slight, and the
5 quality of communication using nonlinear circuit 10 is not degraded significantly. Differences between actual power supply control unit 15 applied voltages shown in line L704 and power supply control unit 15 applied voltage set values shown in line L703 in transient periods tend
10 to become apparent when the actual applied voltage is lower than the applied voltage set value.

Disclosure of Invention

20 Problems to be Solved by the Invention

[0010] However, with conventional nonlinear circuit 10, each time new information related to an amplifier 12 output voltage target value is input from power supply set value input terminal 14 to power supply control unit 15, the
25 power supply control unit 15 applied voltage set value shown in line L703 makes a transition. If applied voltage set values used by power supply control unit 15 make

frequent transitions – that is, if the valid period of individual applied voltage set values is short – many transient periods will occur, and therefore an increase in transmit/receive signal distortion will become
5 apparent as regards amplifier 12 output power, and the communication quality of a radio communication apparatus equipped with nonlinear circuit 10 will degrade.

[0011] FIG.5 is a timing chart showing the voltage, etc., in each component part of nonlinear circuit 10 when the
10 channel A slots shown in line L901 (a_{i-1} , a_i , a_{i+1} , a_{i+2}) and channel B slots shown in line L902 (b_{j-1} , b_j , b_{j+1} , b_{j+2}) are code division multiplexed and then input from transmit/receive signal input terminal 11 to amplifier 12. As can be seen from FIG.5, the boundaries between
15 slots in channels A and B do not coincide in the timing. Line L903 shows amplifier 12 output power target values ($P_{i-1,j-1}$, $P_{i,j-1}$, $P_{i,j}$, $P_{i+1,j}$, $P_{i+1,j+1}$, $P_{i+2,j+1}$, $P_{i+2,j+2}$), line L904 shows power supply control unit 15 to amplifier 12 applied voltage set values ($V_{i-1,j-1}$,
20 $V_{i,j-1}$, $V_{i,j}$, $V_{i+1,j}$, $V_{i+1,j+1}$, $V_{i+2,j+1}$, $V_{i+2,j+2}$), and line L905 shows the applied voltages actually supplied from power supply control unit 15 to amplifier 12.

[0012] In FIG.5, since the channel A boundaries between slots and the channel B boundaries between slots do not
25 coincide in the timing, the applied voltages actually supplied from power supply control unit 15 to amplifier 12 in line L905 have a greater amount of variation and

longer transient periods than in the case of a single channel - that is, line L704. As a result, transmit/receive signal distortion increases as regards amplifier 12 output power, and a problem arises of degradation of the communication quality of a radio communication apparatus equipped with nonlinear circuit 10. In FIG.5, a case is illustrated in which two channels are code division multiplexed, but if the number of multiplexed channels is further increased, transmit/receive signal distortion will increase significantly as regards amplifier 12 output power, and the problem of degradation of the communication quality of a radio communication apparatus equipped with nonlinear circuit 10 will become more readily apparent.

[0013] It is an object of the present invention to provide a nonlinear circuit and nonlinear amplification method whereby, when a transmit/receive signal in which a plurality of channels whose inter-slot boundary arrival times do not coincide are multiplexed is amplified by means of a nonlinear element, timings at which the set value of an applied voltage or applied current supplied to the nonlinear circuit is caused to make a transition are selected, thereby reducing the number of times these set values are caused to make a transition, and furthermore, an applied voltage or applied current actually supplied to the nonlinear element is made to reach the selected set value sooner, and the occurrence of distortion due

to transmit/receive signal amplification is suppressed, as well as a radio communication apparatus equipped with this nonlinear circuit.

5 Means for Solving the Problem

[0014] A nonlinear circuit according to the present invention employs a configuration equipped with a nonlinear element that amplifies an input signal in which a plurality of channels whose inter-slot boundary arrival times do not coincide are multiplexed; a control section that controls a voltage or current supplied to the nonlinear element; and a selection section that selects timings at which the control section causes a set value of the aforementioned voltage or current to make a transition.

Advantageous Effect of the Invention

[0015] According to the present invention, the above-described timings are selected as appropriate, as a result of which the number of occurrences of transient periods are reduced, and individual transient periods are also shortened, enabling distortion occurring in a transmit/receive signal due to amplification by a nonlinear circuit to be significantly reduced.

25

Best Mode for Carrying Out the Invention

[0017] Embodiments of the present invention will now be

described in detail with reference to the accompanying drawings as appropriate.

[0018]

(Embodiment 1)

5 FIG. 6 is a block diagram showing the configuration of a nonlinear circuit 100 according to Embodiment 1 of the present invention. Nonlinear circuit 100 has a transmit/receive signal input terminal 101, an amplifier 102, a transmit/receive signal output terminal 103, 10 operating condition input terminals 104, a power supply control unit 105, timing signal input terminals 106, and an operating section 110. Nonlinear circuit 100 is installed in a radio communication apparatus such as a mobile phone or similar mobile station, a base station, 15 or the like, and amplifies transmit signals or received signals of that radio communication apparatus.

[0019] Operating section 110 has an operation determination section 111 and a timing selection section 112, and controls the operation of power supply control 20 unit 105.

[0020] A transmit/receive signal code division multiplexed with channel A and channel B whose inter-slot boundaries do not coincide in the timing is input to transmit/receive signal input terminal 101 from a signal processing section (not shown). The transmit/receive signal input to transmit/receive signal input terminal 101 is input to amplifier 102.

- [0021] Amplifier 102 is a nonlinear amplifier comprising a general-purpose low-noise amplifier or the like that amplifies a code division multiplexed transmit/receive signal input from transmit/receive signal input terminal 101 based on preset gain and then outputs the amplified signal to transmit/receive signal output terminal 103. The gain of amplifier 102 can be adjusted as appropriate, but in this embodiment it is assumed that the gain is fixed.
- 10 [0022] A signal processing section (not shown) is connected to transmit/receive signal output terminal 103. An amplified transmit/receive signal input to the signal processing section from transmit/receive signal output terminal 103 undergoes predetermined signal processing, 15 and is then transmitted as a radio signal or decoded as a data signal.
- [0023] A plurality of operating condition input terminals 104 are provided, and information indicating the channel A signal level and information indicating the channel B signal level are input to terminals thereamong. These items of information indicating the individual channel signal levels are then input to power supply control unit 105 and operation determination section 111.
- 25 [0024] Power supply control unit 105 is supplied with continuous power from a power supply section (not shown), and based on information indicating the channel A signal

level and information indicating the channel B signal level input from operating condition input terminal 104, calculates the transmit/receive signal level in a case where the transmit/receive signals of these channels are 5 code division multiplexed. Using this calculated signal level as the set value of the power supply voltage to be applied to amplifier 102, power supply control unit 105 supplies an applied voltage using that set value to amplifier 102. If power supply control unit 105 is 10 notified by timing selection section 112 that a set value different from the calculated signal level is to be used for the applied voltage supplied to amplifier 102, power supply control unit 105 supplies amplifier 102 with an applied voltage using the set value notified from timing 15 selection section 112 in accordance with that notification. In power supply control unit 105, also, transient periods occur in the same way as with conventional amplifier 12 in the event of applied voltage set value transitions.

20 [0025] A plurality of timing signal input terminals 106 are provided, to one of which a timing signal A indicating that an inter-slot boundary has arrived for a channel A transmit/receive signal is input, and to another of which a timing signal B indicating that an inter-slot boundary has arrived for a channel B transmit/receive signal is input. Timing signals A and B input to terminals 25 among timing signal input terminals 106 are input to timing

selection section 112. Timing signal A and timing signal B, a transmit/receive signal in which channel A and channel B are code division multiplexed input from transmit/receive signal input terminal 101 to amplifier 102, and information indicating the signal level of a channel A transmit/receive signal and information indicating the signal level of a channel B transmit/receive signal input from operating condition input terminals 104 to power supply control unit 105 and 10 operation determination section 111, are linked respectively. Therefore, by monitoring timing signal A and timing signal B, operating section 110 can ascertain the condition of transmit/receive signals input to amplifier 102 and power supply control unit 105 and so 15 forth.

[0026] Operation determination section 111 performs time series accumulation and monitoring of information indicating channel specific signal levels input from operating condition input terminals 104, and determines 20 the channel specific signal level cycles. Based on the determined channel specific signal level cycles, operation determination section 111 predicts a signal level after either a channel A or channel B signal level input from an operating condition input terminal 104 makes 25 a transition. Then, operation determination section 111 calculates the signal level of a transmit/receive signal code division multiplexed at that predicted

post-transition signal level, and inputs this calculated post-transition transmit/receive signal level to timing selection section 112 as occasion requires.

[0027] By performing time series accumulation and monitoring of timing signal A and timing signal B input from timing signal input terminals 106, timing selection section 112 predicts the transmit/receive signal level transition timing in a case where the respective channel transmit/receive signals are code division multiplexed.

5 Based on this predicted transition timing and the signal level of a post-transition transmit/receive signal input from operation determination section 111, timing selection section 112 calculates the signal level of a code division multiplexed transmit/receive signal

10 immediately after timing signal A is input and the signal level of a code division multiplexed transmit/receive signal immediately after timing signal B input following timing signal A is input. Then, taking into consideration the input interval between timing signal A and timing

15 signal B, and the signal level after timing signal A is input and the signal level after timing signal B is input, timing selection section 112 selects the more suitable of timing signal A or timing signal B for adjusting the transmit/receive signal level. Furthermore, when the

20 non-selected timing signal is input from a timing signal input terminal 106, timing selection section 112 notifies power supply control unit 105 so that the signal level

25

set value of the transmit/receive signal after the selected timing signal input thereafter is input is used.

[0028] Next, the operation of nonlinear circuit 100 will

be described in detail with reference to FIG.7. FIG.7

5 is a timing chart showing voltage set values and actual applied voltages in the component parts of nonlinear circuit 100 when the channel A slots (a_{i-1} , a_i , a_{i+1} , a_{i+2}) shown in line L201 and the channel B slots (b_{j-1} , b_j , b_{j+1} , b_{j+2}) shown in line L202 are code division

10 multiplexed and then input from transmit/receive signal input terminal 101 to amplifier 102.

[0029] The channel A slots (a_{i-1} , a_i , a_{i+1} , a_{i+2}) shown in line L201 are the same as the line L901 slots (a_{i-1} ,

ai, a_{i+1} , a_{i+2}) shown in FIG.5, and the channel B slots (b_{j-1} , b_j , b_{j+1} , b_{j+2}) shown in line L202 are the same as the channel B slots (b_{j-1} , b_j , b_{j+1} , b_{j+2}) shown in line L902. Therefore, FIG.7 shows showing the applied

voltage set values, etc., in each component part of nonlinear circuit 100 in the case where the

20 transmit/receive signals shown in FIG.5 are amplified by nonlinear circuit 100.

[0030] In FIG.7, the boundaries between slots in channels A and B do not coincide in the timing. Also, in FIG.7,

line L203 shows timing signal A giving notification of

25 the arrival of an inter-slot boundary of channel A input from timing signal input terminal 106 to timing selection section 112, and line L204 shows timing signal B giving

notification of the arrival of an inter-slot boundary of channel B input likewise.

[0031] Line L205 shows amplifier 102 output power target values. In line L205, since amplifier 102 output power target values differ due to the superimposition of the channel A slots (a_{i-1} , a_i , a_{i+1} , a_{i+2}) shown in line L201 and the channel B slots (b_{j-1} , b_j , b_{j+1} , b_{j+2}) shown in line L202, the notation "P_{k-1}, P_k, P_{k+1}, P_{k+2}, P_{k+3}, P_{k+4}, P_{k+5}" is used for the amplifier 102 output voltage target values.

[0032] Line L206 shows set values of applied voltages supplied to amplifier 102 by power supply control unit 105. In line L206, also, since power supply control unit 105 applied voltage set values differ due to the superimposition of the channel A slots (a_{i-1} , a_i , a_{i+1} , a_{i+2}) shown in line L201 and the channel B slots (b_{j-1} , b_j , b_{j+1} , b_{j+2}) shown in line L202, the notation "V_{k-1}, V_k, V_{k+1}, V_{k+2}, V_{k+3}, V_{k+4}, V_{k+5}" is used for the amplifier 102 output voltage target values. Applied voltage set values V_k, V_{k+2}, and V_{k+5} in line L206 are indicated by dotted lines. Applied voltage set values V_k, V_{k+2}, and V_{k+5} are the same as applied voltage set values V_{i-1,j-1}, V_{i+1,j}, and V_{i+2,j+2} respectively in line L904 shown in FIG. 5.

[0033] Line L207 shows applied voltages actually supplied to amplifier 102 from power supply control unit 105. In line L207 transient periods T_{resp,k}, T_{resp,k+2},

and $T_{resp,k+4}$ are shown, and the applied voltages in line L905 shown in FIG.5 are indicated by dotted lines. In line L207, also, taking the transient periods shown in line L905 in FIG.5 as a basis, periods shorter than those 5 periods are indicated by the notation "T_{short,k}, T_{short,k+2}, T_{short,k+4}."

[0034] The operation of each component part of nonlinear circuit 100 will now be described, referring to FIG.5 as appropriate, taking the example of the slot a_{i+1} period 10 in line L201 shown in FIG.7.

[0035] At the time when the channel A transmit/receive signal slot transits from slot a_i to slot a_{i+1} , information indicating the slot a_{i+1} signal level is input from operating condition input terminal 104 to power supply 15 control unit 105 and operation determination section 111, and at the same time, timing signal A_{i+1} is input from timing signal input terminal 106 to timing selection section 112.

[0036] In power supply control unit 105, when information 20 indicating the slot a_{i+1} signal level is input from operating condition input terminal 104, set value V_{k+2} of the applied voltage to be supplied to amplifier 102 is calculated.

[0037] On the other hand, in operation determination 25 section 111, when information indicating the slot a_{i+1} signal level is input from operating condition input terminal 104, the signal level of slot b_{j+1} that is due

to arrive next is predicted with reference to the signal levels of each channel A slot and the signal levels of each channel B slot accumulated up to that time, and based on this predicted value, the signal level of a transmit/receive signal when slot a_{i+1} and slot b_{j+1} are code division multiplexed is calculated. Operation determination section 111 then inputs this calculated signal level of a transmit/receive signal when slot a_{i+1} and slot b_{j+1} are code division multiplexed directly to timing selection section 112. It is also possible for the slot b_{j+1} signal level predicted value, the calculated value of the signal level of a transmit/receive signal when slot a_{i+1} and slot b_{j+1} are code division multiplexed, and the like, to be generated by a component part other than operation determination section 111, or set beforehand, and to be input from operating condition input terminal 104 to operation determination section 111.

[0038] Thus, timing signal A_{i+1} , and the signal level of a transmit/receive signal when slot a_{i+1} and slot b_{j+1} are code division multiplexed, are input respectively to timing selection section 112. Timing selection section 112 accumulates timing signals A and B input from timing signal input terminals 106 and their input times, and the signal level of a transmit/receive signal input from operation determination section 111, as a time series, and by referencing these accumulated timing signal A and B times, predicts the input times of timing signal B_{j+1} .

due to be input next. Timing selection section 112 then compares the signal level of a transmit/receive signal when slot a_{i+1} and slot b_{j+1} are code division multiplexed immediately after timing signal A_{i+1} is input, and the 5 signal level of a transmit/receive signal when slot a_{i+1} and slot b_{j+1} are code division multiplexed immediately after timing signal B_{j+1} is input, and also compares the period from when timing signal A_{i+1} is input until timing signal B_{j+1} is input, and the period from when timing 10 signal B_{j+1} is input until timing signal A_{i+2} is input, and selects the period in which the signal level is higher (the highest value) and the period from timing signal B_{j+1} to timing signal A_{i+2} is longer as the appropriate period. Then timing selection section 112 notifies power 15 supply control unit 105 that transmit/receive signal level set value V_{k+3} is to be used in the selected period. In this embodiment, the period with the higher signal level is the longer period, but if, for example, a period that has a high signal level and is shorter and a period 20 that has a low signal level and is longer are compared, the period that has the higher signal level and is shorter will be selected. If the period that has the higher signal level and is shorter is selected as the appropriate period, this is because, in transmit/receive signal amplification 25 by amplifier 102, although the amplification efficiency falls, the occurrence of distortion is reduced.

[0039] On receiving notification to use applied voltage

set value V_{k+3} , power supply control unit 105 rejects applied voltage set value V_{k+2} in accordance with that notification, and uses applied voltage set value V_{k+3} immediately after the arrival of the boundary between 5 slot a_i and slot a_{i+1} in channel A. Therefore, in transient period $T_{resp,k+2}$, the applied voltage actually supplied to amplifier 102 from power supply control unit 105 continues to rise without falling, and consequently distortion due to transmit/receive signal amplification 10 by amplifier 102 is suppressed. Moreover, the applied voltage actually supplied to amplifier 102 from power supply control unit 105 can reach the corresponding set value V_{k+3} in a short time. That is to say, using nonlinear circuit 100 enables the applied voltage to be made to 15 reach set value V_{k+3} by power supply control unit 105 earlier by period $T_{short,k+2}$ in line L207 shown in FIG. 7 than in the case where conventional nonlinear circuit 10 is used.

[0040] Thus, according to nonlinear circuit 100 of this 20 embodiment, even when a transmit/receive signal in which channel A and channel B whose inter-slot boundary arrival times do not coincide are multiplexed is amplified by means of amplifier 102, which is a nonlinear element, by continually reducing the number of times the set value 25 of an applied voltage supplied to amplifier 102 is caused to make a transition, and selecting a more appropriate applied voltage set value, the generation of

transmit/receive signal distortion dependent upon amplification by amplifier 102 can be suppressed, and the actual applied voltage can be made to reach the selected applied voltage set value in a shorter time. Therefore, 5 if a radio communication apparatus is equipped with nonlinear circuit 100 according to this embodiment, better communication quality can be maintained even in an adverse communication environment.

[0041] Also, according to nonlinear circuit 100 of this 10 embodiment, timing selection section 112 selects the timing at which power supply control unit 105 causes a voltage set value to make a transition in synchronization with the arrival time of a boundary between slots in a plurality of channels, thereby enabling the operation 15 of the selection section to be simplified.

[0042] Furthermore, according to nonlinear circuit 100 of this embodiment, timing selection section 112 selects the timing at which power supply control unit 105 causes a voltage set value to make a transition in synchronization 20 with the arrival time of a boundary between slots in a plurality of channels, and also predicts the highest value of the voltage set value in the period between the time at which timing is selected and the time at which timing is next selected, and notifies power supply control unit 25 105 of the predicted highest value and causes the voltage set value to make a transition to the highest value, as a result of which the applied voltage set value used by

power supply control unit 105 is always maintained at the highest value, thereby enabling the occurrence of distortion to be effectively suppressed in input signal (transmit/receive signal) amplification by amplifier 102, 5 which is a nonlinear element.

[0043] Moreover, according to nonlinear circuit 100 of this embodiment, in a transient period until the voltage actually supplied to amplifier 102 reaches the set value, timing selection section 112 does not select the timing 10 for causing that set value to make a transition, thereby making it possible to avoid a situation in which the next transient period begins before the current transient period ends, and to prevent the successive occurrence of transient periods over a long interval.

15 [0044] Also, a radio communication apparatus according to this embodiment, being equipped with nonlinear circuit 100, enables communication quality to be improved in radio communications.

[0045] Nonlinear circuit 100 according to this 20 embodiment may be modified or adapted as described below.

[0046] For nonlinear circuit 100 according to this embodiment, a case has been described in which the voltage of a transmit/receive signal is amplified by amplifier 102, but the present invention is not limited to this 25 case, and the current of a transmit/receive signal may be amplified using a nonlinear circuit element such as a transistor in amplifier 102, for example. Also, both

the voltage and current of a transmit/receive signal may be amplified by amplifier 102.

[0047] Furthermore, for nonlinear circuit 100 according to this embodiment, a case has been described in which 5 the signal level of a transmit/receive signal input to amplifier 102 makes a transition depending on the superimposition condition of slots of each channel, but the present invention is not limited to this case, and may also be applied to cases in which, for example, the 10 signal level of a transmit/receive signal makes a transition depending on an increase or decrease in the number of channels multiplexed in a transmit/receive signal, or depending on variation of the peak power to average power ratio of a transmit/receive signal, a change 15 of the modulation method, or variation of the modulation speed. Nonlinear circuit 100 can also provide the above-described actions and effects in such cases.

[0048] In this embodiment, a case has been described in which timing selection section 112 gives notification 20 to power supply control unit 105 for the use of applied voltage set value V_{k+3} immediately after the arrival of the boundary between slot a_i and slot a_{i+1} in channel A, but the present invention is not limited to this case, and timing selection section 112 may, for example, cause 25 an applied voltage set value transition by power supply control unit 105 only when either timing signal A or timing signal B is input, and not cause an applied voltage set

value transition when the other timing signal is input. Specifically, in FIG. 7, timing selection section 112 may give notification to power supply control unit 105 for the use of applied voltage set value V_k when timing signal 5 A_i is input, and give notification to power supply control unit 105 for the continued use of applied voltage set value V_k when timing signal B_j is input. If this is done, timing selection section 112 need only distinguish between timing signal A and timing signal B, enabling 10 the configuration and operation of operating section 110 to be simplified, and also enabling the power supply voltage actually applied to amplifier 102 to be made to reach the relevant set value, and stabilized, in a short time. However, in FIG. 7, if timing selection section 112 15 gives notification to power supply control unit 105 for the use of applied voltage set value V_{k+2} when timing signal A_{i+1} is input, and gives notification to power supply control unit 105 for the continued use of applied voltage set value V_{k+2} when timing signal B_{j+1} is input, 20 the applied voltage set value will be kept low in the period from timing signal A_{i+1} until timing signal A_{i+2} , resulting in a problem of increased distortion due to transmit/receive signal amplification by amplifier 102. Therefore, to counter this problem, it is desirable for 25 measures to be taken such as providing a lower limit for applied voltage set values.

[0049]

(Embodiment 2)

FIG.8 is a block diagram showing the configuration of a nonlinear circuit 300 according to Embodiment 2 of the present invention. In nonlinear circuit 300, a trigger generation section 311 is newly added to nonlinear circuit 100 according to Embodiment 1. Therefore, since almost all the configuration elements of nonlinear circuit 300 perform similar functions to corresponding configuration elements of nonlinear circuit 100, descriptions of such configuration elements that perform similar functions are omitted to avoid duplication.

[0050] When timing signal A or timing signal B is input from a timing signal input terminal 106, trigger generation section 311 inputs a trigger to timing selection section 112 at preset timing.

[0051] Timing selection section 112 performs the same kind of operation as described in Embodiment 1, conditional upon the input of a trigger from trigger generation section 311, and notifies power supply control unit 105 of the applied voltage set value and the timing for causing a transition of that set value.

[0052] Next, the operation of nonlinear circuit 300 according to this embodiment, and more particularly the operation of trigger generation section 311 and timing selection section 112, will be described in detail with reference to FIG.9.

[0053] FIG.9 is a timing chart showing voltage set values,

actual applied voltages, etc., in each component part of nonlinear circuit 300 when the channel A slots shown in line L401 (a_i-1, a_i, a_i+1, a_i+2) and channel B slots shown in line L402 (b_j-1, b_j, b_j+1, b_j+2) are code division 5 multiplexed and then input from transmit/receive signal input terminal 101 of nonlinear circuit 300 to amplifier 102.

[0054] FIG.9 corresponds to FIG.7, with line L401 identical to line L201, line L402 identical to line L202, 10 line L403 identical to line L203, line L404 identical to line L204, and line L406 identical to line L205. FIG.9 and FIG.7 differ in that there is no line in FIG.7 corresponding to line L405 in FIG.9, applied voltage set value V'_{k+3} in line L407 in FIG.9 is applied voltage set 15 value V_{k+3} in line L206 in FIG.7, and transient period $T_{resp,k+2}$ in line L206 in FIG.7 does not occur in line L408 in FIG.9. Line L405 in FIG.9 shows triggers input from trigger generation section 311 to timing selection section 112.

20 [0055] As can be seen by comparing line L403 with line L405, trigger generation section 311 is set so as to input a trigger to timing selection section 112 once for every two inputs of timing signal A. When a trigger is input from trigger generation section 311, timing selection 25 section 112 operates as follows, in the same way as in Embodiment 1. That is to say, by performing time series accumulation and monitoring of timing signal A and timing

signal B input from timing signal input terminals 106, timing selection section 112 predicts the timing of a transition of the signal level of a transmit/receive signal in a case where transmit/receive signals of each 5 channel are code division multiplexed. Based on this predicted transition timing and the signal level of a post-transition transmit/receive signal input from operation determination section 111, timing selection section 112 calculates the signal level of a code division 10 multiplexed transmit/receive signal immediately after timing signal A is input and the signal level of a code division multiplexed transmit/receive signal immediately after timing signal B input following timing signal A is input. Then, taking into consideration the 15 input interval between timing signal A and timing signal B, and the signal level after timing signal A is input and the signal level after timing signal B is input, timing selection section 112 selects the more suitable of timing signal A or timing signal B for adjusting the 20 transmit/receive signal level. Furthermore, when the non-selected timing signal is input from a timing signal input terminal 106, timing selection section 112 notifies power supply control unit 105 so that the signal level set value of the transmit/receive signal after the 25 selected timing signal input thereafter is input is used.

[0056] By having a trigger Tk input from trigger generation section 311 to timing selection section 112,

the line L407 applied voltage set value becomes V_{k+1} immediately after the arrival of the boundary between slot a_{i-1} and slot a_i in channel A. Then, since a trigger is not generated by trigger generation section 311 when
5 the boundary between slot a_i and slot a_{i+1} arrives in channel A, the line L407 applied voltage set value is kept at $V'_{k+3}=V_{k+1}$. Next, since a trigger T_{k+4} is generated by trigger generation section 311 when the boundary between slot a_{i+1} and slot a_{i+2} arrives in channel
10 A, the line L407 applied voltage set value is caused to make a transition to V_{k+4} . Thus, in this embodiment, transient period $T_{resp,k+2}$ in line L206 in FIG.7 does not occur in line L408, and the number of applied voltage set value transitions by power supply control unit 105
15 can be seen to have been reduced.

[0057] Thus, according to nonlinear circuit 300 of this embodiment, generation of a trigger by trigger generation section 311 is a precondition for an applied voltage set value transition by power supply control unit 105, and
20 therefore the number of occurrences of transient periods for an applied voltage actually supplied to amplifier 102 can be reduced by adjusting the trigger generation timing of trigger generation section 311. As a result, the occurrence of transmit/receive signal distortion due
25 to amplification by amplifier 102 can be significantly suppressed.

[0058] Also, according to nonlinear circuit 300 of this

embodiment, the provision of trigger generation section 311 allows greater design and setting flexibility for timing selection section 112 and power supply control unit 105, and enables a significantly wider range of 5 distortion and efficiency settings to be made with regard to transmit/receive signal amplification by nonlinear circuit 300.

[0059] If trigger generation section 311 is configured by combining logic circuits such as OR and AND circuits, 10 various kinds of trigger can be generated, enabling more precise conditions to be applied to the operation of trigger generation section 311.

[0060] The present application is based on Japanese Patent Application No.2003-361257 filed on October 21, 15 2003, the entire content of which is expressly incorporated by reference herein.

Industrial Applicability

[0061] A nonlinear circuit, radio communication 20 apparatus, and nonlinear amplification method according to the present invention provide for timings at which the set value of an applied voltage or applied current supplied to a nonlinear element is caused to make a transition to be selected by a control section, enabling 25 the number of times the control section causes the set value to make a transition to be reduced, and therefore have an effect of enabling distortion occurring in a

transmit/receive signal due to amplification by a nonlinear circuit to be reduced, and are useful for mobile stations, base stations, and so forth, in a radio communication system.
